Citation: van Poppelen NM, Cassoux N, Turunen JA, et al. The pediatric and young adult choroidal and ciliary body melanoma genetic study, a survey by the european ophthalmic oncology group. *Invest Ophthalmol Vis Sci*. 2024;65(4):12. <https://doi.org/10.1167/iovs.65.4.12>

PURPOSE. To explore the genetic background of choroidal and ciliary body melanoma among children and young adults, with special focus on *BAP1* germline variants in this age group.

METHODS. Patients under the age of 25 and with confirmed choroidal or ciliary body melanoma were included in this retrospective, multicenter observational study. Nuclear BAP1 immunopositivity was used to evaluate the presence of functional BAP1 in the tumor. Next-generation sequencing using Ion Torrent platform was used to determine pathogenic variants of *BAP1*, *EIF1AX*, *SF3B1*, *GNAQ* and *GNA11* and chromosome 3 status in the tumor or in DNA extracted from blood or saliva. Survival was analyzed using Kaplan-Meier estimates.

RESULTS. The mean age at diagnosis was 17 years (range 5.0–24.8). A germline *BAP1* pathogenic variant was identified in an 18-year-old patient, and a somatic variant, based mainly on immunohistochemistry, in 13 (42%) of 31 available specimens. One tumor had a somatic *SF3B1* pathogenic variant. Disomy 3 and the absence of a *BAP1* pathogenic variant in the tumor predicted the longest metastasis-free survival. Males showed longer metastasis-free survival than females ($P = 0.018$).

CONCLUSIONS. We did not find a stronger-than-average *BAP1* germline predisposition for choroidal and ciliary body melanoma among children and young adults compared to adults. Males had a more favorable survival and disomy 3, and the absence of a *BAP1* mutation in the tumor tissue predicted the most favorable metastasis-free survival. A

BAP1 germline pathogenic variant was identified in one patient (1%), and a somatic variant based mainly on immunohistochemistry in 13 (42%).

Keywords: children, adolescents, pediatric, uveal melanoma, *BAP1* gene, germline mutation, monosomy 3

Uveal melanoma (UM) is the most common primary intraocular malignancy among adults¹ with an estimated overall incidence of 6-7 per million in the Western world.² The incidence varies from two to eight cases per million in whites, depending on latitude.^{3,4} Congenital UM is extremely rare, with only a few patients in the literature.⁵⁻⁹ Pediatric UM (PUM), which affects children and young adults (variably defined as <21 to 25 years) is also rare and comprises <1% to 2% of all UM.¹⁰⁻¹⁶

PUM and adult UM differ in some characteristics. Both are located primarily in the choroid, followed by iris and ciliary body,¹¹⁻¹³ but the incidence of iris melanoma among young adults is higher.¹⁵ The mean tumor diameter is smaller in young adults than in patients >60 years.¹⁵ Higher percentage of females was evident in our large collaborative Pediatric Choroidal and Ciliary Body Melanoma Study of 299 PUM¹⁷ in line with a prior meta-analysis,¹⁰ whereas the prevalence of UM in adults is somewhat higher in males than in females.²

Most^{11,12,15,18} but not all¹⁴ series report that PUM has a lower metastatic rate and better prognosis than adult UM. In The Pediatric Choroidal and Ciliary Body Melanoma Study,¹⁷ boys had a more favorable survival than girls, but this difference was not observed among young adults (18-24 years). Mortality increased with ciliary body involvement and a higher TNM (tumor, node, metastasis) stage.^{10,13,17} Moreover, extraocular extension and congenital oculo(dermal) melanocytosis were unfavorable prognostic factors.¹⁷

UM with monosomy 3 has a worse prognosis than that with disomy 3.¹⁹ Monosomy 3 is often accompanied by a gain of chromosome 8q,^{20,21} a combination associated with even worse prognosis.^{22,23} The tumor suppressor gene *BRCA1*-associated protein 1 (*BAP1*), located on chromosome 3, plays an important role in prognosis of UM.²⁴ *BAP1* is a deubiquitinating enzyme involved in the DNA repair mechanism.²⁵ *BAP1* additionally contributes to cell regulation, metabolism, and chromosome stability.²⁶⁻²⁸ Loss of *BAP1* in UM is associated with higher transcriptome levels of *CD38* (*CD38* molecule), *HLA-DRA* (major histocompatibility complex, class II, DR alpha), *IDO-1* (indoleamine 2,3-dioxygenase 1), and *LAG-3* (lymphocyte activating 3), which are associated with immune suppressive pathways.²⁹ Exactly how *BAP1* contributes to the development of metastasis of UM is still unclear because of its many functions and interactions. Immunohistochemically demonstrable loss of nuclear *BAP1* is a surrogate for a pathogenic variant³⁰ and strongly associated with metastasis and survival.^{31,32} Grading systems for *BAP1* IHC in lieu of a dichotomous score have been described, but none of the patients without metastatic disease had absence of *BAP1*.³³

Not only somatic but also germline pathogenic variants in *BAP1* are described in patients with UM. Patients carrying a *BAP1* germline variant develop other cancers besides UM, especially mesothelioma, clear cell renal cell carcinoma, and cutaneous melanoma.³⁴⁻³⁶ Such a *BAP1* tumor predisposition syndrome is present in about 2% of UM patients.³⁴ No significant difference was found in the age of onset of UM in

patients with a null and a missense *BAP1* variant.³⁵ However, the study did not include many patients with PUM, leaving the frequency of germline variants in this group unknown.

In The Pediatric Choroidal and Ciliary Body Melanoma Study,¹⁷ which did collect new genetic data, we reported that monosomy 3 was found in eight (54%) of 15 children 11 to 17 years old and in six (24%) of 25 young adults 18 to 24 years old. One of five patients in both groups had tested positive for somatic *BAP1* pathogenic variants. The data suggested that the pathogenesis of PUM might differ by age group.

The present extended study aims to confirm, or exclude, that monosomy 3 predicts a higher risk for metastasis in PUM. We hypothesize that monosomy 3 is correlated with poor prognosis, as has been shown in adults as well.^{19,22} The other primary aim was to identify *BAP1* somatic and germline variants in PUM. A secondary aim was to screen for other known UM driver mutations.

MATERIAL AND METHODS

Patient Selection

Eligibility for this retrospective cohort study included all patients in whom a choroidal and ciliary body melanoma was diagnosed at an age younger than 25 years and for whom a sample for genetic study and at least the following anonymous data were available: birth date, date of diagnosis, gender, treatment type, presence or absence of local or systemic tumor recurrence, last survival status, date of last known status, and cause of death (UM, second cancer, or nonmalignant cause) determined by reviewing the patient charts, registry data, histopathologic samples, and death certificates. Patients with iris melanomas were ineligible. All treatment methods were eligible. Informed consent from all patients was obtained before the samples were processed. This investigation was approved by the institutional review boards of the participating centers as required and it adhered to the tenets of the Declaration of Helsinki and was approved by the Rotterdam local ethics committee.

Data Collection

Anonymous data on consecutive eligible patients were collected from members of the European Ophthalmic Oncology Group. The data additionally acquired included presence of congenital oculo(dermal) melanocytosis or neurofibromatosis; visual acuity and intraocular pressure at diagnosis and at last visit; tumor thickness, largest basal diameter, ciliary body involvement, extraocular extension, distance from the center of the fovea and the margin of the optic disc, cell type, cytogenetic features; dates of any local tumor recurrence, secondary enucleation, and metastasis; and second primary malignancies. We staged the tumors according to the eighth edition of the TNM system of the American Joint Committee on Cancer.^{37,38} Participat-

ing ocular oncology services submitted their data through a secure survey website from patients diagnosed between 1968 and 2018.

Blood was withdrawn or saliva was collected from patients and parents whenever possible. Germline testing was performed on retinal tissue of the histopathologic specimen in cases where no blood or saliva was available. Tumor tissue from enucleated eyes (n = 50), resections (n = 6), or biopsy specimens (n = 2) were used for BAP1 immunohistochemistry (IHC) or DNA isolation when available.

DNA Extraction

Targeted next-generation sequencing (NGS) was performed on DNA extracted from blood, saliva, formalin-fixed paraffin-embedded tissue (FFPE) of the retina and the tumor. For DNA isolation of blood, the QIAmp DNA Blood kit was used (Qiagen, Hilden, Germany) according to the manufacturer's protocol. DNA isolation from saliva was performed with the Oragene DNA OG-500 kit for collection of human DNA (DNA Genotek, Ottawa, ON, Canada) following manufacturer's protocol. FFPE sections were used to isolate retinal and tumor tissue. Depending on the size of the tumor, four to nine sections 5 µm thick were deparaffinized and stained with hematoxylin before DNA isolation. DNA extraction was performed as described with 5% Chelex (Bio-Rad, Hercules, CA, USA) and Proteinase K (Qiagen).³⁹

DNA was stored at -20C°, and concentrations were measured using the Quant-iT dsDNA Assay Kit, high sensitivity (Thermo Fisher Scientific, Waltham, MA, USA) as described by the manufacturer. Moreover, prior histopathological and genetic data were directly obtained of 28 PUM patients from the participating institutes.

Immunohistochemistry

BAP1 IHC was performed on FFPE tumor tissue as described previously.³⁰ Sections 4 to 5 µm thick were used. All slides, except one, were evaluated by an ophthalmic pathologist (RMV) and one of the authors (NvP) for the presence of nuclear BAP1 expression. Agreement on all samples was reached. Lack of nuclear BAP1 immunoreactivity was taken to indicate a pathogenic variant in the BAP1 gene.³⁰

Mutation Analysis

Germline analysis of BAP1 was performed on blood, or on retinal FFPE tissue from the histopathologic slides. NGS was performed using the Ion Torrent platform (Thermo Fisher Scientific). A panel covering exon 4 and 5 of GNAQ and GNA11, exon 1 and 2 of EIF1AX, exon 14 of SF3B1, and all exons of BAP1 was used as described before.³⁹ The sequencing results were analyzed with Integrative Genomics Viewer (IGV; Broad Institute, Cambridge, MA, USA). A variant was considered when it occurred in at least 10% of the reads with a minimal read count of 50.

Copy Number Variation

Copy number variation analysis of chromosome 3 was performed with 21 amplicons covering highly polymorphic regions with a minor allele frequency of at least 45% as described previously.³⁹ Scatter plots were used to display the frequency of variant coverage compared to total coverage. These data were extracted from the variant calling files.

Statistical Analysis

All analyses were performed with IBM SPSS Statistics Version 28.0.1.0 (IBM, Armonk, NY, USA). Kaplan-Meier plots and the log-rank test were used to compare survival between groups. P < 0.05 was considered significant.

RESULTS

A total of 84 patients were enrolled, and specimens from 58 of them were collected from 12 ocular oncology centers to be analyzed at the Erasmus Medical Center (Rotterdam, the Netherlands), whereas samples from 26 French patients were analyzed at the Institute Curie (Paris, France). The samples that were sent to the Erasmus Medical Center were either blood, saliva, or FFPE tissue. Blood was collected from 12 patients, FFPE material was available for 36 patients, and saliva was used for analysis from nine patients. From one patient both blood and FFPE tissue were used. Thus 59 samples from 58 patients were analyzed at the Erasmus Medical Center. Fine-needle aspiration biopsy was performed on three patients (4%) before definitive treatment.

Disomy	9 (50.0%)	32 (100%)
Loss of heterozygosity	6 (33.3%)	0 (0%)
Monosomy	3 (16.7%)	0 (0%)

Clinical Characteristics

Our cohort consisted of 46 (55%) females and 37 (45%) males (data not available for one patient) with a mean age at diagnosis of 17 years (range 5.0–24.8; median = 18; Table 1, Fig. 1). The female/male ratio (1:0.8) was not different from 1 ($P = 0.38$, binomial test). The age at diagnosis was comparable between males and females ($P = 0.53$, independent samples t -test). The presence of extraocular extension and ciliary body involvement were comparable between genders ($P = 0.95$ and $P = 0.71$, respectively, Pearson's χ^2 test).

Histopathological Features

Most of the 34 UM with a known cell type were of spindle cell type ($n = 17$ [50%]). One-third consisted of mixed cell type ($n = 11$ [32%]), and six (18%) were epithelioid cell type.

Ciliary body involvement was present histopathologically in 41% (34/83), and extraocular extension was described in seven (8.5%) of the 82 UM of which the data were available.

The median largest tumor basal diameter was 12.0 mm with a mean of 12.7 mm (range 4.0–20.4), and the median tumor thickness was 7.7 mm (mean = 8.1, range 1.0–20.0). The TNM anatomical category was described in 56 cases. The most common was T2a ($n = 15$) followed by T3a ($n = 9$) and T1a ($n = 7$). The highest TNM category was T4d, in one patient.

Treatment

Treatment data were available for 83 (99%) of patients and consisted of surgery, radiotherapy, or a combination of both (Table 2, Fig. 1). Surgery included enucleation in 50 patients

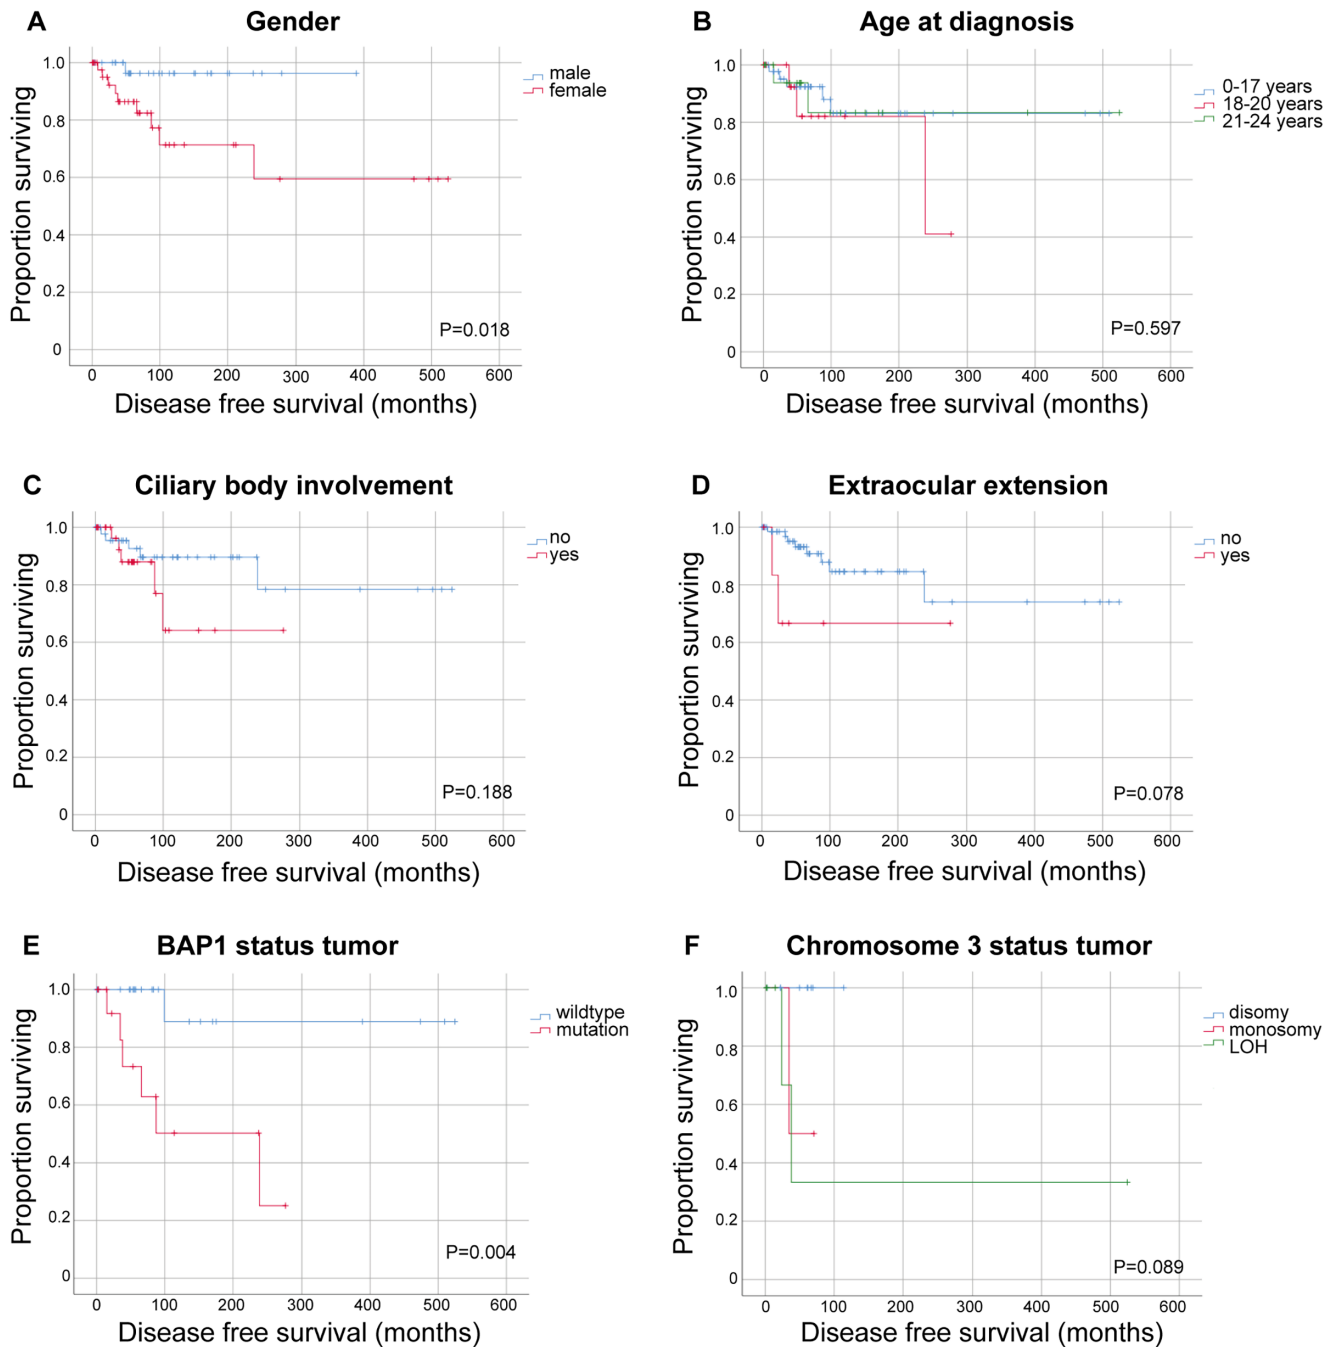

FIGURE 2. Kaplan-Meier estimates of disease-free survival in children and young adults with uveal melanoma. Metastasis-free survival in months according to (A) gender, (B) age at diagnosis, (C) ciliary body involvement, (D) extraocular extension, (E) *BAP1* status of the tumor, and (F) chromosome 3 status of the tumor. LOH, loss of heterozygosity. *P* values from log-rank test. Ticks indicate censored observations.

(60%), of whom 10 received adjuvant treatment, endoresection in two patients followed by enucleation, local resection, and iridocyclectomy in one patient. Enucleation was also performed secondarily after primary treatment. Radiotherapy was performed in 41 patients (50%), of whom ruthenium brachytherapy was used most often, followed by proton beam therapy. Fourteen patients (17%) were treated with a combination of radiotherapy and surgery: ruthenium brachytherapy and resection ($n = 4$), external beam radiotherapy and enucleation ($n = 3$), proton beam therapy and enucleation ($n = 2$), proton beam therapy and endoresec-

tion ($n = 1$), cyber knife and enucleation ($n = 1$), ruthenium and enucleation ($n = 1$), and iodine and enucleation ($n = 1$). One patient was treated with iridocyclectomy, iodine radiotherapy, and enucleation. Extraocular extension was present in three patients who underwent combination therapy.

Metastases and Survival

Almost 80% of patients were alive at the time of data collection ($n = 65$ [77%]), and 15 patients had died (18%).

The latest status of four patients (5%) was unknown. Of 12 patients who developed metastases, eight have died of them. One patient died of another cause, and the cause of death for six patients was reported as unknown and presumed to be UM. Two patients underwent liver surgery for metastatic disease. One patient developed another primary malignancy, an intestinal adenocarcinoma. We did not have enough data to confirm that females had metastases more frequently (22% vs. 6%; $P = 0.058$, Fisher's exact test).

Mean metastasis-free survival (MFS) was 9.0 years (range 0.01 to 43.7) and longer than the median MFS (5.5 years) because of a few very long survival times. Overall survival was comparable to MFS with a mean of 9.1 years and a median of 5.8 years (range 0.01–43.7). Males survived longer than females ($P = 0.018$, log-rank test, Fig. 2A). No overall difference in DFS among three age groups (0–17, 18–20, and 21–24 years; Fig. 2B) or when divided into younger and older than 18 ($P = 0.56$) was observed. No difference in DFS was confirmed by extraocular extension or ciliary body involvement (Figs. 2C, 2D).

When DFS was compared by gender among different age groups, a difference in the age group of 0–17 years was noted (Fig. 3). However, these subgroups are small and a lead time bias could not be excluded.

BAP1 Immunohistochemistry

BAP1 IHC was performed on 31 sections (Fig. 4), none of them were obtained from fine-needle aspiration biopsy. No nuclear staining was observed in 13 (42%), interpreted as the presence of a *BAP1* pathogenic variant. The other 18 UM showed preserved nuclear *BAP1* immunoreaction (58%). These samples included six patients who underwent both surgical treatment, as well as radiotherapy, of which one sample (3%) did not show nuclear staining. The last-mentioned patient was treated with enucleation and external beam therapy because extraocular extension was present in this case. Metastatic disease developed in this patient.

Genetic Analysis

NGS (Erasmus MC) was performed on DNA isolated from FFPE tissue of seven patients with PUM; none of them were irradiated. *GNAQ/GNA11* somatic pathogenic variants were detected in four of them, *BAP1* variants in three, and an *SF3B1* variant was found in one tumor (Table 2). No *EIF1AX* pathogenic variants were identified. Genetic analysis performed at the Curie Institute revealed three *BAP1* mutations (two wildtypes, of which one was irradiated before genomic testing), four *GNAQ/GNA11* mutations and no *SF3B1* nor *EIF1AX* mutations.

A reliable result of germline analysis of *BAP1* was obtained from 12 blood samples, seven saliva samples, and eight FFPE samples. In one patient both blood and FFPE was tested, so 26 patients were tested for germline *BAP1* analysis. The prevalence of the *BAP1* germline pathogenic variants was 4% (1/26, 95% CI –0.04 to 0.13). The only germline c.1708C>G, p.(Leu570Val) pathogenic variant was detected in an 18-year-old female who underwent enucleation. This variant results in a frameshift with a stop codon after 40 amino acids. The *BAP1* variant in this patient was described previously.⁴⁰ No germline variants were detected in *GNAQ*, *GNA11*, *SF3B1*, or *EIF1AX* (Table 2).

FIGURE 3. Kaplan-Meier estimates of disease-free survival in children and young adults with uveal melanoma. Survival is compared between males and females by age at diagnosis subgroups. P values from log-rank test are unadjusted. Ticks indicate censored observations.

The MFS of patients with a somatic *BAP1* mutation (no *BAP1* expression using IHC or mutation detected with sequencing) was shorter compared to the MFS of those with wild-type *BAP1* (Fig. 2E).

Analysis of chromosome 3 was performed on 27 germline samples (blood, FFPE, or saliva), all with disomy 3. Disomy 3 in the tumor was shown in nine of 18 PUM (50%), three (17%) showed a loss of chromosome 3 (monosomy 3), and

FIGURE 4. *BAP1* immunohistochemistry of formalin-fixed paraffin-embedded tissue of uveal melanoma (magnification $\times 400$). Lost (left) and preserved nuclear *BAP1* immunoreactivity (right).

six (33%) showed a loss of heterozygosity (95% CI [0.37, 1.29]).

Tumors with disomy 3 developed metastasis less frequently than tumors with loss of heterozygosity ($P = 0.027$, not corrected for multiple pairwise comparisons). Log-rank testing across all groups did not show a difference in log rank test (Fig. 2F).

DISCUSSION

In our collaborative study, we were able to enroll 84 children and young adults with a PUM and genetic data from 13 centers. The number is reasonable given that this infrequent tumor is even more rare in children than in adults.¹⁵ In our series, 14% of patients developed metastatic disease by 15 years, which is roughly comparable to a previous study in which metastasis 15 years after diagnosis was described in 19% of patients 20 years old or younger at diagnosis of PUM.¹³ One patient developed metastatic disease even after 20 years in the aforementioned study. In another study, metastasis at 10 years occurred in 9% and at 20 years in 20% of children.¹¹ The follow-up time in our cohort was relatively short with a median of 5.8 years.

In previous studies, females had PUM more frequently than males,¹⁰ although this was not significant in most studies,^{11,12,17} including the present one. We observed a longer DFS in young males compared to females ($P = 0.018$), indicating a more favorable prognosis in the former. This is in line with previous studies in which gender was an independent predictor of survival,^{10,17} of which one showed this to be the case, especially in children younger than 17 years.¹⁰

Of the genetic features analyzed, predictors for survival among children and young adults in our study was chromosome 3 status and presence of a *BAP1* pathogenic variant in the tumor. The prognosis was better when both copies of chromosome 3 were present. This is in line with the previously reported series in which monosomy 3 was associated with worse survival.^{19,22} *BAP1* pathogenic variants in the tumor were observed in 45% of the patients, and they had a shorter DFS ($P = 0.004$).

Not only do somatic *BAP1* mutations occur in UM, but also germline pathogenic variants in *BAP1* are described.

Germline *BAP1* variants are described in other studies to be present in about 2% of unselected patients, and in about 4% of patients who had a UM diagnosed before the age of 40 years.^{34,41} In another group of young patients with UM (age < 30 years) the incidence of *BAP1* germline mutations was slightly higher (7%).⁴² We did not observe a higher percentage of germline *BAP1* pathogenic variants in PUM, compared to the latter studies. This is in line with the observation that the age of diagnosis in adults is not lower for patients with an *BAP1* germline pathogenic variant as compared to UM patients with a somatic *BAP1* mutation.⁴¹ More research is needed to further evaluate the development of UM in children and young adults. This study did not shed light on the difference in biology because of no high prevalence of germline *BAP1* mutations in this patient group.

In the *BAP1* tumor predisposition syndrome, the age at diagnosis of cancer in general is associated with the type of *BAP1* variant: it was lower in patients harboring a null variant compared to a missense variant. However, this difference was not observed specifically for UM and renal cell carcinoma.³⁵ This suggests that the pathophysiology of *BAP1* mutations in UM is different compared to some other *BAP1*-associated cancers. This could explain the not-higher-than-average frequency of germline variants in *BAP1* in PUM.

The main strength of our study is its collaborative nature with a relatively high number of patients with PUM. Its main but unavoidable weakness is its retrospective nature, resulting in variable practices as regards prognostic biopsy specimens and methods of prior genetic analysis across time and centers, for which reason full germline and somatic genetic data were not available from all patients. Moreover, the genetic analyses used in this study were performed in two centers, and only the tumors that had evidence of non-functional *BAP1* were evaluated further for germline aberrations, which are caveats in our study. Tumors might have been incorrectly scored as *BAP1* positive because of tumor heterogeneity which has been demonstrated for *BAP1* in UM.⁴³ This could be the case when an area with loss of nuclear *BAP1* was not subject to evaluation of *BAP1* IHC. This does not apply to the *BAP1* negative cases; when there is nuclear *BAP1* loss in an area, the tumor should be coded *BAP1* negative.

It should be noted that the number of patients with ciliary body involvement is relatively high in this study. Moreover, present results do not apply to children younger than five years of age, and the pathogenesis of PUM remains incompletely known pending further research to elucidate all underlying genetic predisposing factors.
